

# Lecture 5 Worksheet: Complexity Analysis

A **step** is any unit of work with bounded execution time (it doesn't keep getting slower with growing input size).

We classify algorithm complexity by classifying the **order of growth** of a function  $f(N)$ , where  $f$  gives the number of steps the algorithm must perform for a given input size.

Big O definition: if  $f(N) \leq C * g(N)$  for large  $N$  values and some fixed constant  $C$ , then  $f(N) \in O(g(N))$

1

Let  $f(N) = 2N^2 + N + 12$

If we want to show  $f(N) \in O(N^3)$ , what is a good lower bound on  $N$ ? Let's have  $C=1$ .

$N > 3$

If we want to show  $f(N) \in O(N^2)$ , do we pick 1, 2, or 4 for the  $C$ ? After picking  $C$ , should we choose for  $N$ 's lower bound?

$C=4, N > 3$

What is more informative to show?

$f(N) \in O(N^3)$  or  $f(N) \in O(N^2)$ ?

$O(N^2)$

Somebody claims  $f(N) \in O(N)$ , offering  $C=30$  and  $N > 0$ . Suggest an  $N$  value to counter their claim. **1000**

2

Each of the following list operations are either  $O(1)$  or  $O(N)$ , where  $N$  is  $\text{len}(L)$ . Circle those you think are  $O(N)$ .

$L.\text{insert}(0, x)$

$L.\text{pop}(0)$

$x = L[0]$

$x = \text{max}(L)$

$x = \text{len}(L)$

$L.\text{append}(x)$

$L.\text{pop}(-1)$

$L2.\text{extend}(L)$

$x = \text{sum}(L)$

$\text{found} = x \text{ in } L$

3

```
def search(L, target):
    for x in L:
        if x == target: #line A
            return True
    return False
```

*assume this is asked unless otherwise stated*

Let  $f(N)$  be the number of times line A executes, with  $N = \text{len}(L)$ . What is  $f(N)$  in each case?

**Worst Case** (target is at end of list):  $f(N) = \underline{N}$

**Best Case** (target is at beginning of list):  $f(N) = \underline{1}$

**Average Case** (target in middle of list):  $f(N) = \underline{\sim N/2}$

4

```
def selection_sort(L):
    for i in range(len(L)):
        idx_min = i
        for j in range(i, len(L)):
            if L[j] < L[idx_min]:
                idx_min = j
        L[idx_min], L[i] = L[i], L[idx_min] # swap values at i and idx_min
```

if this runs  $f(N)$  times, where  $N = \text{len}(L)$ ,

then  $f(N) = \underline{1+2+\dots+N = N*(N+1)/2}$

```
nums = [2, 4, 3, 1]
selection_sort(nums)
print(nums)
```

The complexity of selection sort is

$O(\underline{N^2})$

5

```
# assume L is already sorted, N=len(L)
def binary_search(L, target):
    left_idx = 0 # inclusive
    right_idx = len(L) # exclusive
    while right_idx - left_idx > 1:
        mid_idx = (right_idx + left_idx) // 2
        mid = L[mid_idx]
        if target >= mid:
            left_idx = mid_idx
        else:
            right_idx = mid_idx

    return right_idx > left_idx and L[left_idx] == target
```

how many times does this step run when N = 1? N = 2? N = 4? N = 8?

0    1    2    3

If f(N) is the number of times this step runs, then f(N) =  $\log_2(N)$

The complexity of binary search is  $O(\log N)$

6

```
def merge(L1, L2):
    rv = []
    idx1 = 0
    idx2 = 0

    while True:
        done1 = idx1 == len(L1)
        done2 = idx2 == len(L2)

        if done1 and done2:
            return rv

        choose1 = False
        if done2:
            choose1 = True
        elif not done1 and L1[idx1] < L2[idx2]:
            choose1 = True

        if choose1:
            rv.append(L1[idx1])
            idx1 += 1
        else:
            rv.append(L2[idx2])
            idx2 += 1

    return rv
```

```
def merge_sort(L):
    if len(L) < 2:
        return L
    mid = len(L) // 2
    left = L[:mid]
    right = L[mid:]
    left = merge_sort(left)
    right = merge_sort(right)
    return merge(left, right)

merge_sort([4, 1, 2, 3])
```

merge([1, 3], [2, 4]) will return [1, 2, 3, 4].  
 merge(L1, L2) implements an  $O(N)$  algorithm. But how can we measure the size of the input?  $N = \text{len}(L1) + \text{len}(L2)$

If we double the list size, there will be \_\_\_ more level(s). Level count grows  $O(\log N)$ . Work per level is  $O(N)$ . merge\_sort complexity:  $O(N \log N)$

7

```
nums = [...]
first100sum = 0

for x in nums[:100]:
    first100sum += x
print(first100sum)
```

If we increase the size of nums from 20 items to 100 items, the code will probably take 5 times longer to run.

If we increase the size of nums from 100 to 1000, will the code take longer? Yes / No

The complexity of the code is  $O(1)$ , with  $N=\text{len}(\text{nums})$ .
